ABSTRACT
This study aims to evaluate serum levels of the Dehydroepiandrosterone sulfate (DHEA-S) and its relationship with some sex hormones such as Follicle stimulating hormone (FSH), Luteinizing hormone (LH), prolactin and testosterone hormone and the infertility type in some infertile Iraqi men.

Blood and seminal fluid samples from (60) idiopathic male infertile and (60) healthful individuals as a control group aged (18 to 60) year were collected from private clinics. Serum hormones (DHEA-S, FSH, LH, prolactin and testosterone) were measurement using Enzyme Linked Immunosorbent Assay (ELISA).

The levels of DHEA-S, FSH, LH and prolactin are significantly higher (P≤0.01) expect of the testosterone level when compared with control group. High significant differences (P≤0.01) were recorded when comparing the hormonal levels (DHEA-S, FSH, LH, prolactin and testosterone) according to the age groups. There are significant differences (P≤ 0.01) in levels of (DHEA-S, FSH, LH, prolactin and testosterone) in the infertility period. Smoker infertile men have high levels (P≤ 0.05) in the DHEA-S and LH while have low levels in the prolactin hormones compared with control. Patients with family history have shown significant differences (P≤0.05) in the levels of DHEA-S, FSH, LH and prolactin.

In conclusion, this study revealed significantly increase in the DHEA-S levels in the infertile men and negative correlation between DHEA-S and FSH. Therefore, DHEA-S has important role in the diagnosis and follow up of the male infertility.

Keywords: Male Infertility, DHEA-S, Sex hormones

I. INTRODUCTION
Infertility is the inability to become pregnant after one year of normal, unprotected sexual intercourse with the same partner [1]. Or it is a condition in which males are unable to achieve pregnancy after one year of normal unprotected intercourse, often with a sperm count of less than 20 million/ml [2]. Infertility primarily affects the reproductive system of males and females at equal rates [3].

Dehydroepiandrosterone (DHEA-S) is the most abundant steroid hormone in the human body, and it is called anti-aging hormone or youth hormone because it delays the aging process [4]. It is a natural steroid hormone consisting of 19 carbon atoms that is produced by body tissues. It is secreted mainly from the zona reticularis of the adrenal cortex. It is also produced to a lesser extent by the brain and gonads, as it is derived from cholesterol as a hormone-generating substance [5].

Natural steroid hormones are derived from cholesterol and can be categorized according to their different physiological roles through activation of their specific intracellular receptors into five classes: glucocorticoids, mineralocorticoids, androgens, estrogens, and progestogens [6].

Follicle-stimulating hormone (FSH) is a member of the glycoprotein family that has a central and essential role in reproduction. (FSH) is a hormone released by the anterior pituitary gland by stimulation of gonadotrophin secretion and possibly other factors. It is released in a pulsatile manner and is partially regulated by glycoproteins, including activin and inhibin. FSH reflects the status of spermatogenesis as a result of feedback between the testis, hypothalamus and pituitary gland [7].

LH is a glycoprotein that regulates testosterone synthesis by Leydig cells. The levels of these hormones are under the control of negative feedback from gonad [8]. In contrast, serum FSH has a longer shelf life, and fluctuations in serum levels are less pronounced. If an abnormal LH value is obtained in one sample, three samples of serum can be collected within a 20-minute interval between one sample and another [9].

Testosterone is responsible for normal growth, development of male reproductive organs, and maintenance of secondary sexual characteristics, as high levels within the testicles are a prerequisite for sperm production and development, improving their motility and improving epididymal function, and there is some controversy about the required relative levels [10].

The hormone prolactin, secreted by the anterior pituitary gland, has a detrimental effect on male fertility when it exceeds the physiological level [11]. It has an important role in the formation of sperm in males, prolactin may have a physiological role in regulating testosterone [12], and hyperprolactinemia leads to infertility in about 11% of males [13]. Where Prolactin controls both LH and FSH production through the regulation of GnRH, as an elevated level of prolactin

Hormonal levels of infertile males by age:

The results of the current study showed a significant increase (P≤0.01) in the level of DHEA-S hormone 906.05±12.407 for the age group 31-40 years compared with the hormone level 848.03±9.951 for the age group >30-20 years, and the hormone level 794.89±12.239 for the age group ≥ 41 years. The significant differences (P≤0.01) in the level of testosterone ng/ml were 2.788 ± 0.356, 2.71 ± 0.461, 2.075 ± 0.202 for age groups <30-20 years, 31-40 years and age group ≥41 years, respectively. And statistically significant differences (P≤0.01) in FSH levels (mIU/ml) 15.490 ± 4.045, 11.758 ± 4.593, 18.061 ± 3.495, respectively, for the same age groups mentioned above. And significant differences (P≤ 0.01) in LH levels (mIU/ml) were 8.869±2.646, 14.872±2.834 (ng/ml) and Prolactin 14.872±2.834 (ng/ml) when compared with the control groups 4.565 ± 2.325, 4.632 ± 1.110, 9.303 ± 2.429, respectively, and as shown in Table (2).

The effect of infertility on the concentration of hormones:

The results showed that the level of DHEA-S hormone was significantly increased at the probability level of P ≤ 0.01 among infertile patients (867.9376 ± 21.290) compared with the level of the hormone in normal subjects (763.524 ± 25.726). The results of the current study indicate a decrease in the level of Testosterone hormone 2.5658 ± 0.331 in sterile males when compared with the control group 3.960 ± 0.274. While it was found that there was a significant increase (P≤0.01) in the level of hormones FSH 14.620 ± 4.143 (mIU/ml), LH of 8.869 ± 2.646 (mIU/ml) and Prolactin 14.872 ± 2.834 (ng/ml) when compared with the control groups 4.565 ± 2.325, 4.632 ± 1.110, 9.303 ± 2.429, respectively, and as shown in Table (1).

Hormonal levels of infertile males according to the infertility period:

The results of the study showed that the differences were not significant when comparing the level of DHEA-S between age groups, age group ≤10, age group 11-20 and age group ≥21, (850.22±22.678, 804.794±20.459, 945.77±12.761), respectively. Significant differences (P≤ 0.01) in hormone levels of Testosterone (ng/ml) 2.709±0.573, 2.536±0.607, and FSH (mIU/ml) 14.216±2.177, 13.07±1.937, 20.455±2.577. and Prolactin (ng/ml) 16.794±1.797, 12.664±1.495, 10.351±0.981. respectively for age groups ≤10 years old, age group 11-20 years and age group ≥21 years. Also, non-significant differences were recorded in the level of LH hormone (mIU/ml) 8.632 ± 1.445, 9.375 ± 1.818, 8.86 ± 1.317, respectively for age groups ≤10 years old, age group 11-20 years and age group ≥21 years. and as shown in Table (3).

Hormonal levels of infertile males according to smoking:

There were no significant differences (P=0.01) when comparing the level of DHEA-S in smokers (939.446 ± 23.3691) and non-smokers (844.101 ± 48.315). There were significant differences (P<0.01) in the level of LH hormone (mIU/ml) when comparing the level of LH 11.368 ± 2.144 in smokers with the level of LH 8.036 ± 2.137 in non-smokers. Also, the differences were significant (P<0.01) in the level of the hormone ng/ml Prolactin when comparing the level of the hormone 13.308 ± 1.841 in the smokers with the level of the hormone 15.394 ± 2.215 in the non-smokers. The results of the current study did not record significant differences between the level of the hormone Testosterone (ng/ml) when comparing the level of the hormone 2.635 ± 0.559 in smokers with a level of 2.542 ± 0.532 in non-smokers. The same applies to FSH hormone (mIU/ml), as it was found that there were no significant differences in the level of the hormone when comparing between smokers 14,741 ± 2.477 and non-smokers 14,580 ± 2.399, and as shown in Table (4).

Hormonal levels of infertile males by family history:
The results showed that there was a significant difference (P≤0.05) when comparing the level of DHEA-S 817.34 ± 50.11 in people with a family history with DHEA-S level 874.05 ± 76.05 in people without a family history. The results also showed a significant difference (P≤0.05) in the level of Testosterone (ng/ml) when comparing the level of the hormone 2.357 ± 0.376 in people with a family history of infertility with the level of the same hormone 2.607 ± 0.323 in people without a family history of infertility. For the same level of significance mentioned above, it was found that there was a significant difference in the level of the hormone Prolactin (ng/ml) when comparing its level of 12.18 ± 2.851 among people with a family history of infertility with the level of the same hormone 15.411 ± 3.767 in normal people with no family history of infection. The differences were significant (P<0.01) in the level of FSH hormone (mlu/ml) when comparing its level 19.825 ± 2.543 among people with a genetic family history of infertility compared with the level of FSH 13.58 ± 2.073 in normal people without family problems of infertility, as well as for the LH hormone (mlu/ml), it was found that there was a significant difference (P<0.01) in the level of this hormone when comparing its level 7.414 ± 1.993 among people with a family history of infertility with the level of the hormone 9.160 ± 1.714 in healthy people and not family history, and as shown in Table (5).

IV. DISCUSSION

The effect of infertility on the concentration of hormones:
The results of the current study are in agreement with the study conducted by [16], and the result of the current study is in agreement with the study conducted by [17], in Iran. The study showed that there was a significant increase in the level of FSH hormone in infertile men, while the level of testosterone and LH hormone was lower when compared with the control groups. Which showed an increase in FSH hormone with a decrease in Testosterone, while there was no effect on LH. In general, increased FSH levels are a good indicator of germinal epithelial cell destruction and are usually associated with azoospermia or oligospermia. Low testosterone levels are signs of hypogonadism, hypothalamic or pituitary gland [16].
Hyperprolactinemia reduces male fertility by suppressing the action of testosterone, as hyperprolactinemia is well known to lower libido and lead to reduced sperm production, on the other hand, hyperprolactinemia may be caused by a number of pathological factors, such as, disorders of Hypothalamus, pituitary gland tumor, hypothyroidism, and hypogonadism and this may mean some disturbances in the stages of spermatogenesis in infertile patients [18]. The independent secretion of DHEA-S from the adrenal gland and its metabolism in peripheral tissues may explain this finding [19]. The results of the current study in the level of DHEA-S and testosterone hormone and according to the type of infertility agreed with the study [20], and the study that he conducted [21]. Since testosterone is important in regulating germ cell growth, it becomes necessary to measure the level of testosterone to monitor male infertility [22]. Sperm formation requires the presence of gonadotropins and testosterone [23]. Spermatogenesis is associated with higher levels of intracellular testosterone, and our results were in agreement with that of [24], thus not only explaining impaired spermatogenesis but also reduced function of Leydig cells and causes of pre-testicular azoospermia were also suspected [24]. And it was shown by a previous study that was conducted that there is no direct correlation between the level of DHEA-S in the serum and the number of sperms [21], the independent secretion of DHEA-S from the adrenal gland and its metabolism in the peripheral tissues may explain this result [19].

Hormonal levels of infertile males by age:

The influence of age on infertility varies and interacts with many genetic, social, psychological and health factors related to the patient's history [25]. And it did not find an association or effect on the age factor with infertility, as this was not statistically significant, while the results of [26]. It found that males had a higher rate of infertility between 20-29 years (46%), followed by 30-39 years (40%). While [27], specifically indicated in his study that the incidence of infertility at the age of less than 30 years is higher in men, followed by 30-34 years and decreases with age. The results of a study also found that the vast majority of sterile patients ranged in age from 20-29 years [28]. Their results were attributed to early marriage, semen quality, and ejaculation process, which gradually decrease with age. It begins to decline after the age of 35 [29]. As well as the presence of many other genetic disorders that have an effect on the reproductive process, as is the case in the X chromosome [30]. DHEA-S can turn into an androgen or estrogen, and not all of its vital functions have been determined so far. The concentration of DHEAS in the blood reaches its peak around the age of 25 years and then declines steadily during the following years, due to its half-life. With its long duration and high concentration in the blood, DHEAS levels remain the same 24 hours a day. This makes DHEAS an important diagnostic tool for both scientific research and clinical diagnosis. Furthermore, concentrations of DHEAS can change by many factors, such as production Internal medicine, hormonal supplements, many types of medications, and many types of disease conditions [31].

Hormonal levels of infertile males according to the period of infertility:

The effect of post-marital infertility differed on hormonal behavior. Although no studies have been conducted on the effect of this factor on concentrations of specific hormones, the effect of age can depend mainly on the fact that testosterone tends to decrease with increasing infertility as well as an increase in the level of FSH. These findings can also be associated with poor mental status and emotional distress in patients.

Hormonal levels of infertile males according to smoking:

The results of the current study agreed with the results of the study conducted by [32], and differed with the results of the study conducted by [33]. Many other studies have shown that the relationship of smoking and male infertility is uncertain, ie. The issue of smoking and its effect on infertility did not have a clear effect and the results of studies varied from one study to another [34], and studies showed that there are no reliable effects among male smokers on semen parameters. Nicotine may modulate the pituitary axis by enhancing the production of cortisol, growth hormone, oxytocin and vasopressin, which in turn inhibit prolactin and luteinizing hormone [35]. In a study looking at the effectiveness of tobacco smoking on hormone levels [36], average levels of estradiol were observed to be higher, and the average levels of prolactin, follicle-stimulating hormone (FSH) and LH levels were lower in smokers compared to non-smokers, while the average levels of FSH were not. Testosterone and dehydroepiandrosterone are different. Many components of tobacco smoke have effects on testosterone. Nicotine has been reported to impair the male reproductive hormone system by causing Leydig apoptosis and inhibiting androgen synthesis [37]. Toxins, including lead in tobacco, appear to directly impair spermatogenesis itself as well as sperm function through reproductive axis impairment or testicular degeneration. Also, semen parameters (total number, motility, and morphology) are decreased in fertile smokers compared to infertile non-smokers. Smoking caused a significant decrease in sperm count and morphology. However, it had no significant effect on movement in the study subjects [38].

Hormonal levels of infertile males by family history:

It included several subgroups of infertile subjects which in all cases indicated no family history of infertility. In their survey, this included the chromosomal assessment of the members of the infertility group studied [39]. While some studies have indicated that families with a medical history of infertility and a family history of infertility called PRM1 homozygous PRM1
genetic mutations have a 40% higher risk of infertility than those with no family history of infertility [40].

**Correlation between the concentration of DHEA-S with other hormones:**

The results of the current study agreed with the results of the study conducted by [41], that an increase in the concentration of DHEA-S hormone is associated with a decrease in the concentration of testosterone in the blood [42]. In a study conducted, it was found that there is an elevated chromatin damage in men with low or low androgen status. DHEA and its sulfate ester (DHEA-S) are the two most abundant steroid hormones in humans [43].

In conclusion, this study revealed significantly increase in the DHEA-S levels in the infertile men and negative correlation between DHEA-S and FSH. Therefore, DHEA-S has important role in the diagnosis and follow up of the male infertility.
